Abstract

A lattice formulation of the $O(1, 2)/O(2) \times Z_2$ sigma model is developed, based on the continuum theory presented in the preceding paper. Special attention is given to choosing a lattice action (the “geodesic” action) that is appropriate for fields having noncompact curved configuration spaces. A consistent continuum limit of the model exists only if the renormalized scale constant β_R vanishes for some value of the bare scale constant β . The geodesic action has a special form that allows direct access to the small- β limit. In this limit half of the degrees of freedom can be integrated out exactly. The remaining degrees of freedom are those of a compact model having a β -independent action which is noteworthy in being unbounded from below yet yielding integrable averages. Both the exact action and the β -independent action are used to obtain β_R from Monte Carlo computations of field-field averages (2-point functions) and current-current averages. Many consistency cross-checks are performed. It is found that there is no value of β for which β_R vanishes. This means that as the lattice cutoff is removed the theory becomes that of a pair of massless free fields. Because these fields have neither the geometry nor the symmetries of the original model we conclude that the $O(1, 2)/O(2) \times Z_2$ model has no continuum limit.

1 Introduction

In the preceding paper (denoted here by I) we have outlined the main theoretical features that would characterize the quantized $O(1,2)/O(2) \times Z_2$ sigma model if it had a continuum limit in four dimensions. In this paper we present evidence that the model does not, in fact, have such a limit. The equations of paper I are therefore purely formal and serve only to motivate our procedures in the lattice simulation.

Because lattice simulations of noncompact sigma models have not been performed previously, and because there is evidence that the concept of “universality” of the scaling critical point may not apply to noncompact models, we take special care to develop a lattice action that is appropriate for the $O(1,2)/O(2) \times Z_2$ model. The chief goal of our investigations, which is to determine whether or not there exists an interacting continuum limit of the model, can be reached by computing the dimensionless renormalized coupling constant β_R (eq. (5.12)). An acceptable continuum limit exists only when β_R is zero. From our numerical simulations we determine β_R both from two-point functions, via the effective action formalism, and from current algebra.

In addition to performing direct numerical simulations of the $O(1,2)/O(2) \times Z_2$ model we also develop a useful small- β or “strong coupling” expansion, which permits half of the degrees of freedom to be integrated out exactly. The remaining degrees of freedom form a relatively simple (although somewhat unusual) compact model which is independent of the bare coupling constant. Simulations of this model provide yet another way to study the continuum limit of the full sigma model.

Our numerical results from Monte Carlo simulations of both the full model and its small- β limit indicate that β_R is never zero and hence that there is no interacting continuum limit of the theory. Our results are consistent with the existence of a *noninteracting* continuum limit, i.e., a continuum limit that is a free field theory. This result lends support to the popular conjecture that all scalar field theories in four dimensions are “trivial” (in the technical sense of triviality). However, since this continuum limit has neither the symmetries nor the interactions of the original classical model we conclude that a consistent quantum theory of the $O(1,2)/O(2) \times Z_2$ model does not exist.

2 The massless scalar field. Lattice action and lattice Fourier transforms.

To get our bearings on how to introduce the lattice we look first at a completely soluble system: the free massless scalar field. This system is described by a single real scalar field ϕ , and its Euclidean action is

$$S = \frac{1}{2}\mu^2 \int \phi_{,\mu} \phi_{,\mu} d^4x. \quad (2.1)$$

(We here drop the subscript E introduced in I to distinguish the Euclidean action from the Minkowski one.) The field ϕ is chosen to be dimensionless and the scale factor is made explicit in order to maintain as close a resemblance as possible to the sigma models. The lattice is most simply chosen to be a cubical one having N^4 sites and periodic boundary conditions (4-torus). On such a lattice the action (2.1) takes the differenced form

$$S = \frac{1}{2}\mu^2 a^2 \sum_{\text{links}} [\phi(\text{one end of link}) - \phi(\text{other end of link})]^2 \quad (2.2)$$

where a is the lattice spacing and the links are between adjacent sites in the four principal lattice directions, with periodicity conditions taken into account.

The size, or periodicity distance, of the lattice is

$$L = Na, \quad (2.3)$$

but to the computer this length is irrelevant. The only adjustable constants in the lattice version of the theory are the dimensionless quantities N and β , where β is the coefficient in (2.2):

$$\beta \equiv \mu^2 a^2. \quad (2.4)$$

If μ is to be a finite mass scale then β must vanish as the lattice spacing goes to zero.

The system (2.2) is best studied by introducing the *lattice Fourier transform*. Denote by $\phi_{\alpha\beta\gamma\delta}$ the value of the field ϕ at the lattice site having coordinates $\alpha a, \beta a, \gamma a, \delta a$, with the origin of coordinates taken at a corner of the periodic cube, the coordinate axes being oriented along the principal lattice directions, and $\alpha, \beta, \gamma, \delta$ being integers ranging from 0 to $N - 1$. The lattice Fourier transform is defined by

$$\tilde{\phi}_{klmn} = N^{-2} \sum_{\alpha,\beta,\gamma,\delta} \phi_{\alpha\beta\gamma\delta} \exp \left[\frac{2\pi i}{N} (k\alpha + l\beta + m\gamma + n\delta) \right], \quad (2.5)$$

where k, l, m, n are integers ranging from $-N/2 + 1$ to $N/2$ (N being here assumed to be even). The original periodic field may be regained by taking the inverse Fourier transform

$$\phi_{\alpha\beta\gamma\delta} = N^{-2} \sum_{k,l,m,n} \tilde{\phi}_{klmn} \exp \left[-\frac{2\pi i}{N} (k\alpha + l\beta + m\gamma + n\delta) \right]. \quad (2.6)$$

It is well known that imposition of periodicity in Euclidean time corresponds to studying the field ϕ in a thermal state at temperature $T = 1/kL$, where k is Boltzmann's constant. However, since the cutoff energy arising from the lattice discretization of the system corresponds to a temperature of order $1/ka$, which is N times as big, T may effectively be regarded as vanishing, the thermal state being indistinguishable from the ground state when N is large.

In order to express the lattice action (2.2) in terms of the Fourier transform $\tilde{\phi}_{klmn}$, it is convenient to introduce some abbreviations. The ordered set of integers $(\alpha, \beta, \gamma, \delta)$ will be denoted simply by $\boldsymbol{\alpha}$ and the ordered set (k, l, m, n) by $\mathbf{k}$. The following additional abbreviations are obvious:

$$\mathbf{k} \cdot \boldsymbol{\alpha} = k\alpha + l\beta + m\gamma + n\delta, \quad (2.7)$$

$$\boldsymbol{\alpha} + \boldsymbol{\alpha}' = (\alpha + \alpha', \beta + \beta', \gamma + \gamma', \delta + \delta'), \quad (2.8)$$

$$-\mathbf{k} = (-k, -l, -m, -n), \text{ etc.} \quad (2.9)$$

Now let the symbol $\boldsymbol{\lambda}$ (for links) range over the eight values $(\pm 1, 0, 0, 0)$, $(0, \pm 1, 0, 0)$, $(0, 0, \pm 1, 0)$, $(0, 0, 0, \pm 1)$ and regard all integers as defined *modulo* N . Then, taking note of the double counting of links, rewrite expression (2.2) in the form

$$\begin{aligned} S &= \frac{1}{4}\beta \sum_{\boldsymbol{\alpha}, \boldsymbol{\lambda}} \left(\phi_{\boldsymbol{\alpha}} - \phi_{\boldsymbol{\alpha} + \boldsymbol{\lambda}} \right)^2 \\ &= \frac{1}{4}\beta N^{-4} \sum_{\boldsymbol{\alpha}, \boldsymbol{\lambda}, \mathbf{k}, \mathbf{k}'} \tilde{\phi}_{\mathbf{k}} \tilde{\phi}_{\mathbf{k}'} \left[e^{-(2\pi i/N)\mathbf{k} \cdot \boldsymbol{\alpha}} - e^{-(2\pi i/N)\mathbf{k} \cdot (\boldsymbol{\alpha} + \boldsymbol{\lambda})} \right] \\ &\quad \times \left[e^{-(2\pi i/N)\mathbf{k}' \cdot \boldsymbol{\alpha}} - e^{-(2\pi i/N)\mathbf{k}' \cdot (\boldsymbol{\alpha} + \boldsymbol{\lambda})} \right] \\ &= \frac{1}{4}\beta \sum_{\boldsymbol{\lambda}, \mathbf{k}} \tilde{\phi}_{\mathbf{k}} \tilde{\phi}_{\mathbf{k}}^* \left[2 - e^{(2\pi i/N)\mathbf{k} \cdot \boldsymbol{\lambda}} - e^{-(2\pi i/N)\mathbf{k} \cdot \boldsymbol{\lambda}} \right] \\ &= \frac{1}{2}\beta \sum_{\mathbf{k}} \bar{K}^2(\mathbf{k}) \left| \tilde{\phi}_{\mathbf{k}} \right|^2 \end{aligned} \quad (2.10)$$

where

$$\bar{K}(\mathbf{k}) \equiv \left(2 \sin \frac{\pi k}{N}, 2 \sin \frac{\pi l}{N}, 2 \sin \frac{\pi m}{N}, 2 \sin \frac{\pi n}{N} \right), \quad (2.11)$$

$$\bar{K}^2(\mathbf{k}) \equiv \bar{K}(\mathbf{k}) \cdot \bar{K}(\mathbf{k}). \quad (2.12)$$

The last line of (2.10) follows from the easily verified identity

$$\sum_{\boldsymbol{\lambda}} \left[1 - e^{(2\pi i/N)\mathbf{k} \cdot \boldsymbol{\lambda}} \right] = \sum_{\boldsymbol{\lambda}} \left[1 - e^{-(2\pi i/N)\mathbf{k} \cdot \boldsymbol{\lambda}} \right] = \bar{K}^2(\mathbf{k}) \quad (2.13)$$

and the fact that $\tilde{\phi}_{-\mathbf{k}} = \tilde{\phi}_{\mathbf{k}}^*$.

Note that although the physical continuum momentum corresponding to the integers k, l, m, n is $K(\mathbf{k})/a$ where $K(\mathbf{k}) = (2\pi/N)\mathbf{k}$, it gets replaced on the lattice by $\bar{K}(\mathbf{k})/a$, which equals $K(\mathbf{k})/a$ only in the limit $N \rightarrow \infty$. The sine functions appearing in (2.11) are lattice artifacts stemming from the replacement of derivatives by differences.

With the action recast in the form (2.10) it is an easy matter to compute 2-point functions, with averages defined as in eq. (I.10.5) but adapted for the lattice. For the free field the integrals in (I.10.5) are Gaussian. Since the transformation from the variables $\phi_{\boldsymbol{\alpha}}$ to the variables $\tilde{\phi}_{\mathbf{k}}$ effectively diagonalizes the Gaussian matrix, and since this transformation is unitary with unit Jacobian, one may write down the 2-point function by inspection:

$$\langle \tilde{\phi}_{\mathbf{k}} \tilde{\phi}_{\mathbf{k}'} \rangle = \frac{\delta_{\mathbf{k}, -\mathbf{k}'}}{\beta \bar{K}^2(\mathbf{k})}. \quad (2.14)$$

The general n -point functions are equally easy to obtain. They vanish when n is odd and are expressible as sums of permuted products of 2-point functions when n is even, which is another way of saying that all higher correlation functions vanish for Gaussian probability distributions.

Actual machine computations of the 2-point functions are found to agree very precisely with eq. (2.14) for all values of $\mathbf{k}$ and $\mathbf{k}'$ except $(0, 0, 0, 0)$. The reason $(0, 0, 0, 0)$ is special (apart from the fact that expression (2.14) becomes singular at this value) is that $\tilde{\phi}_{\mathbf{0}}$ represents the *constant component* of ϕ , being N^2 times the average of ϕ over the lattice. The Euclidean action attains its lower bound, namely zero, whenever ϕ is a constant. Moreover, the addition of a constant to ϕ leaves the action unchanged, and hence the integrals over the variable $\tilde{\phi}_{\mathbf{0}}$ diverge. On the computer this divergent degree of integration freedom is eliminated by adding an appropriate constant to ϕ at the end of each Monte Carlo “sweep” of the lattice, in order to keep $\tilde{\phi}_{\mathbf{0}}$ equal to zero. This has the consequence that the Monte Carlo average $\langle \tilde{\phi}_{\mathbf{0}}^n \rangle$ vanishes for all positive integers n . $\tilde{\phi}_{\mathbf{0}}$ could, of course, be held fixed at any other value. Zero is chosen merely for convenience. This fixing is equivalent to fixing the vacuum state, the vacuum being here degenerate just as it is in the case of the $O(1, 2)/O(2) \times Z_2$ model.

If one takes the lattice Fourier transform of (2.14) (remembering $\tilde{\phi}_{\mathbf{0}} = 0$) to obtain the 2-point function directly in ordinary space, one finds that when N is large and $(\boldsymbol{\alpha} - \boldsymbol{\alpha}')^2$ is

small compared to N^2 the 2-point function accurately approximates the continuum Green's function:

$$\langle \phi_{\alpha} \phi_{\alpha'} \rangle \approx \frac{1}{4\pi^2\beta(\alpha - \alpha')^2}, \quad N \gg 1, \quad 0 < (\alpha - \alpha')^2 \ll N^2. \quad (2.15)$$

Note in particular that this function is spherically symmetric. For larger values of $(\alpha - \alpha')^2$, to be sure, the cubical toroidal lattice structure begins to show itself, but it is nontrivial that (2.14) yields (2.15) when $(\alpha - \alpha')^2$ is small despite the fact that $\bar{K}^2(\mathbf{k})$ itself is *not* spherically symmetric. *A remnant of $O(4)$ symmetry remains in the lattice simulation.* We shall see later that the momentum-space 2-point function of the $O(1,2)/O(2) \times Z_2$ model can be accurately represented by an expression of the form (2.14) multiplied by a nonsingular slowly varying function of $\bar{K}^2(k)$. We regard this as a lattice confirmation of the $O(4)$ symmetry, or original Lorentz symmetry, of the continuum model.

3 A difficulty. The $O(1,1)/Z_2 \times Z_2$ model.

The success achieved in simulating the massless free field on the computer prompts one to attempt an analogous simulation of the $O(1,2)/O(2) \times Z_2$ model, based on the similarity of expression (2.1) to the part of the action (I.2.5) that does not involve the Lagrange multiplier. This similarity suggests that the $O(1,2)/O(2) \times Z_2$ lattice action be chosen in the form

$$S = \frac{1}{2}\beta \sum_{\text{links}} \eta_{ab} \left[\phi^a(\text{one end of link}) - \phi^a(\text{other end of link}) \right] \\ \times \left[\phi^b(\text{one end of link}) - \phi^b(\text{other end of link}) \right], \quad (3.1)$$

with the ϕ^a subjected to the constraint

$$\eta_{ab} \phi^a \phi^b = -1 \quad (3.2)$$

(cf. (I.2.8)). In the case of the $O(3)/O(2)$ sigma model, in which ϕ^0 is replaced by ϕ^3 , η_{ab} by δ_{ab} , and the constraint by $\phi^a \phi^a = 1$, this is exactly the choice of lattice action that is usually made. The reason for this is that if the number of dimensions is reduced from four to three the theory becomes formally identical to the statistical theory of the Heisenberg ferromagnet, which is interesting to study in its own right: The action becomes proportional to the spin-interaction Hamiltonian, β becomes the coupling constant divided by temperature, and the functional integral of $e^{-S[\phi]}$ becomes the partition function.

There is, however, a difficulty with the choice (3.1). To show this we digress for a moment by looking at a simpler model, the $O(1,1)/Z_2 \times Z_2$ model, which is obtained from

the $O(1,2)/O(2) \times Z_2$ model by omitting the field ϕ^2 . Equations (I.2.5) and (3.2) continue to hold, but η_{ab} is now given by $(\eta_{ab}) = \text{diag}(-1, 1)$. The configuration space is topologically $\mathbb{R}$, instead of $\mathbb{R}^2$, and can be parameterized by a single variable s , where

$$\left. \begin{aligned} \phi^0 &= \cosh s \\ \phi^1 &= \sinh s. \end{aligned} \right\} \quad (3.3)$$

In terms of s the Euclidean action becomes

$$S = \frac{1}{2}\mu^2 \int s_{,\mu} s_{,\mu} d^4x \quad (3.4)$$

which is that of the massless free field!

The use of two variables, ϕ^0 and ϕ^1 , to describe the massless free field allows us to view it in a new light, and to ask questions that would not have occurred to us if we had confined our attention to only one variable, questions that are relevant also for the $O(1,2)/O(2) \times Z_2$ model. We note first of all that there is a conserved current, which may be read off directly from eq. (I.10.20):

$$\begin{aligned} j_{01\mu} &= \mu^2 (\phi_0 \phi_{1,\mu} - \phi_1 \phi_{0,\mu}) \\ &= \mu^2 [-\cosh s (\sinh s)_{,\mu} + \sinh s (\cosh s)_{,\mu}] \\ &= -\mu^2 s_{,\mu}. \end{aligned} \quad (3.5)$$

The Fourier transform of this current is simply

$$\tilde{j}_{01\mu}(p) = i\mu^2 p_\mu \tilde{s}(p), \quad (3.6)$$

which, in view of the well-known free-particle propagator

$$\langle \tilde{s}(p) \tilde{s}(p') \rangle = \frac{\delta(p + p')}{\mu^2 p^2}, \quad (3.7)$$

leads immediately to the following analog of eq. (I.10.18):

$$\langle \tilde{j}_{01\mu}(p) \tilde{j}_{01\nu}(p') \rangle = \mu^2 \frac{p_\mu p_\nu}{p^2} \delta(p + p'). \quad (3.8)$$

The bare and renormalized Planck masses are seen to be identical for this model, as is to be expected.

As shown in paper I the renormalized Planck mass can also in principle be obtained from any 2-point function, for example from $\langle \phi^1(x) \phi^1(x') \rangle$. This, however, requires the evaluation

of $\langle \phi^0 \rangle$, and this, in turn, requires introduction of a cutoff such as the lattice provides. Let us assume that the correct lattice action for the $O(1,1)/Z_2 \times Z_2$ model is expression (2.2) with ϕ replaced by s . To obtain $\langle \phi^0 \rangle$ it is convenient first to compute $\langle s^2 \rangle$, using

$$s\boldsymbol{\alpha} = N^{-2} \sum'_{\mathbf{k}} \tilde{s}_{\mathbf{k}} e^{-(2\pi i/N)\mathbf{k}\cdot\boldsymbol{\alpha}}, \quad (3.9)$$

where the prime on the summation sign indicates that the term with $\mathbf{k} = 0$ is to be omitted, on the assumption that $\tilde{s}_0$ is held equal to zero. Note that holding $\tilde{s}_0 = 0$ by adding a constant to the free scalar field at the end of each Monte Carlo sweep is equivalent to applying an $O(1,1)$ “boost” to the field at the end of each sweep. This is completely analogous to the procedure that must be adopted in the case of the $O(1,2)/O(2) \times Z_2$ model in order to fix the vacuum state. In that case an $O(1,2)$ boost is applied at the end of each sweep in order to maintain the lattice averages of ϕ^1 and ϕ^2 equal to zero.

Using eq. (2.14), with ϕ replaced by s , and invoking the displacement invariance of the theory, one gets

$$\begin{aligned} \langle s^2 \rangle &= \langle s\boldsymbol{\alpha}^2 \rangle = N^{-4} \sum_{\boldsymbol{\alpha}} \langle s\boldsymbol{\alpha}^2 \rangle = N^{-4} \sum'_{\mathbf{k}, \mathbf{k}', \boldsymbol{\alpha}} \langle \tilde{s}_{\mathbf{k}} \tilde{s}_{\mathbf{k}'} \rangle e^{-(2\pi i/N)(\mathbf{k}+\mathbf{k}')\cdot\boldsymbol{\alpha}} \\ &= N^{-4} \sum'_{\mathbf{k}} \langle \tilde{s}_{\mathbf{k}} \tilde{s}_{-\mathbf{k}} \rangle = F(N)/\beta \end{aligned} \quad (3.10)$$

where

$$F(N) = N^{-4} \sum'_{\mathbf{k}} \bar{K}^{-2}(\mathbf{k}). \quad (3.11)$$

In the Appendix the following easy estimate of $F(\infty)$ is derived:

$$F(\infty) \approx .15. \quad (3.12)$$

This estimate has been confirmed by explicit summation on the computer. $F(N)$ is found to converge rapidly to the value .1549... for N greater than 4. This is an example of a stability property that one frequently encounters in lattice simulations: Important quantities often (although not always!) become independent of N as N is increased.

Because a free field obeys Gaussian statistics one has also

$$\langle s^{2n} \rangle = \frac{(2n)!}{2^n n!} \langle s^2 \rangle^n, \quad \langle s^{2n+1} \rangle = 0, \quad (3.13)$$

whence

$$\langle \phi^0 \rangle = \langle \cosh s \rangle = \sum_{n=0}^{\infty} \frac{1}{(2n)!} \langle s^{2n} \rangle = \sum_{n=0}^{\infty} \frac{1}{2^n n!} \langle s^2 \rangle^n = e^{F(N)/2\beta} \quad (3.14)$$

and

$$\langle \phi^1 \rangle = \langle \sinh s \rangle = 0 \quad (3.15)$$

(cf. (I.7.1)).

Suppose now that instead of proceeding as above one chooses for the lattice action expression (3.1) with $a, b \in \{0, 1\}$. In terms of s this action becomes

$$S = 2\beta \sum_{\text{links}} \sinh^2 \frac{1}{2} [s(\text{one end of link}) - s(\text{other end of link})] . \quad (3.16)$$

When the link differences are small, expressions (3.16) and (2.2) (with ϕ replaced by s) are approximately equal. However, in the functional integral the link differences do not stay small in the continuum limit $a \rightarrow 0, \beta \rightarrow 0$. Consequently the two actions lead to very different results on the computer. This may be seen as follows: Let Δs be the difference between the values of s at opposite ends of one of the links in the sum (3.16). The contribution that this link makes to the sum is $2\beta \sinh^2 \frac{1}{2} \Delta s$. As long as this contribution is of order 1 or less for every link, the field will contribute significantly to the functional integrals in (I.10.5) (with ϕ replaced by s). The dominant fields are therefore characterized by the condition

$$\Delta s \sim 2 \sinh^{-1} \frac{1}{\sqrt{2\beta}} \xrightarrow{\beta \rightarrow 0} -\ln \beta . \quad (3.17)$$

Since the cross-link differences are of order $-\ln \beta$ for small β , one may expect $\langle |s| \rangle$ to be of similar order:

$$\langle |s| \rangle \sim -\ln \beta \quad (3.18)$$

whence

$$\langle \phi^0 \rangle \sim e^{-\zeta \ln \beta} = \beta^{-\zeta} \quad (3.19)$$

for some ζ . Actual machine computations, using the action (3.1), show that ζ is approximately equal to .57.

The difference between expressions (3.14) and (3.19) for $\langle \phi^0 \rangle$ is striking. According to (3.19) $\langle \phi^0 \rangle$ exhibits a weak singularity as $\beta \rightarrow 0$; according to (3.14) it exhibits an essential singularity! Another difference shows up in the computation of the “lattice specific heat,” which is defined by

$$c_L = N^{-4} \left(\langle E^2 \rangle - \langle E \rangle^2 \right), \quad E \equiv S/\beta . \quad (3.20)$$

Using the action (2.2) (with ϕ replaced by s) one obtains trivially

$$c_L = \text{const.} \times \beta^{-2}. \quad (3.21)$$

On the other hand, computations based on (3.1) are found to yield

$$c_L = \text{const.} \times \beta^{-1.88(3)}. \quad (3.22)$$

Both (3.21) and (3.22) show that $\beta = 0$ is the “critical point” of the theory. But the critical exponents differ!¹

These results have immediate implications for the $O(1, 2)/O(2) \times Z_2$ model. Obviously one cannot reach trustworthy conclusions about any theory, on the basis of lattice simulations, unless one can trust the lattice action.

4 The geodesic lattice action

The sensitivity of the above results to the choice of lattice action stems from the fact that the fields in noncompact models undergo huge fluctuations as $\beta \rightarrow 0$. For the $O(1, 2)/O(2) \times Z_2$ model we should like to use an action that is as close as possible to the action (2.2) (with ϕ replaced by s) for the $O(1, 1)/Z_2 \times Z_2$ model. We first note that the link differences in eq. (2.2) are taken directly in configuration space (the real line) whereas those in eq. (3.1) are taken in the embedding space. In our view one should stay in configuration space. But unless the configuration space is flat, as it is for the $O(1, 1)/Z_2 \times Z_2$ model, this criterion is insufficient. One must also deal with the problem of what “preferred” coordinates to choose, if any.

That this problem may be a critical one can be seen by noting that the dominant cross-link differences to which the action (2.2) gives rise satisfy

$$\Delta\phi \sim \frac{1}{\sqrt{\beta}} = \frac{1}{\mu a}. \quad (4.1)$$

Even if one imagines the continuum fields to be C^∞ interpolations of the lattice fields, one sees that in the functional integrals these fields become wildly discontinuous in the limit $a \rightarrow 0$. Their derivatives are even more singular, diverging nearly everywhere like $1/a^2$ as $a \rightarrow 0$.

It is easy to see that in d dimensions the derivatives of the fields diverge nearly everywhere like $a^{-d/2}$ as $a \rightarrow 0$. Thus even when $d = 1$, i.e., in the case of ordinary quantum mechanics, the dominant trajectories are nondifferentiable. This is a well known feature of

¹It is also worth noting that $c_L \rightarrow \infty$ at the critical point already when N is finite. With compact models c_L diverges at the critical point only in the “thermodynamic limit” $N \rightarrow \infty$.

path integration, but it has consequences that are sometimes forgotten. Classically, a system may be described by any convenient variables, and in a transformation from one set of variables to another, derivatives of one set are obtained from those of the other by application of the chain rule. The chain rule is valid, however, only when the derivatives actually exist. In the case of path integration in ordinary quantum mechanics it has been known for years that the transformation laws for lattice derivatives do not involve merely simple Jacobians. Extra terms have to be added to the naïve finite differences suggested by the continuum classical action. In the case of nonlinear sigma models in four dimensions, in which there are no obviously preferred field variables, we do not have any already-worked-out theorems to help us in choosing an appropriate lattice action. The quantum theory of these models simply does not yet exist as a coherent discipline. We are in the position of having to *define* the theory by choosing a specific lattice action *a priori*.

We have chosen to replace the lattice action (3.1) by

$$S = \frac{1}{2}\beta \sum_{\text{links}} \Delta^2 (\phi(\text{one end of link}), \phi(\text{other end of link})) \quad (4.2)$$

where Δ is the geodetic distance (I.3.8) in the configuration space (*not* in the embedding space) between the field values at the two ends of the link. This choice has four attractive features:

1. It can be expressed in terms of any convenient field variables, being independent of which ones are used.
2. It reduces to (2.2) (with ϕ replaced by s) in the case of the $O(1,1)/Z_2 \times Z_2$ model.
3. It is invariant under the actions of the global group, whether $O(1,1)$ or $O(1,2)$ or whatever.
4. When $d = 1$ (ordinary quantum mechanics) it defines, in the continuum limit, a system whose wave function ψ satisfies the (almost) obviously correct Schrödinger equation

$$i\partial\psi/\partial t = \left(-\frac{1}{2}\square + \frac{1}{6}R\right)\psi, \quad (4.3)$$

where $\square$ is the covariant Laplacian operator on the configuration space and R is the curvature scalar.

When $d = 1$ the choice (4.2) is also obtained if one simply interpolates classical solutions of the dynamical equations between the lattice sites and inserts the interpolated ϕ into the

continuum action. For $d > 1$ a strict analog of this procedure would require interpolation of solutions of the classical field equations across lattice *cells*, but we believe that construction of such an analog would be unnecessarily complicated and would yield results not significantly different from those obtained with (4.2). We note also that historical controversies over the term in R in (4.3) are irrelevant here because, for sigma models, R is a constant and affects only the energy zero point.

The action (4.2) can also be used for the $O(3)/O(2)$ model. But in this case the cross-link differences $\Delta\phi^a$ can never be larger than 2, and simulations we have run show that both (4.2) and the conventional action yield results that are qualitatively similar. Both lead to phase transitions as β is decreased: At a certain critical value β_c , of order unity, the average $\langle\phi^3\rangle$, which plays the role of *magnetization*, drops abruptly to small values (which tend to zero as $N \rightarrow \infty$). The precise value of β_c depends on which lattice action is used, but otherwise there is little difference.

There is a quantity that plays the role of “magnetization” for the $O(1,2)/O(2) \times Z_2$ model, namely $\langle\phi^0\rangle^{-1}$. Both (3.1) and (4.2) cause $\langle\phi^0\rangle^{-1}$ to drop to zero as $\beta \rightarrow 0$, but the nature of the dropoff differs profoundly from one action to the other. The reason the $O(3)/O(2)$ model has a phase transition is that its configuration space is compact. $\langle\phi^3\rangle$ drops to zero as soon as the functional integral begins to probe the whole configuration space. The configuration space of the $O(1,2)/O(2) \times Z_2$ model, being noncompact, is never fully probed as long as β is finite. There is always some residual “magnetization” $\langle\phi^0\rangle^{-1}$ and there is no phase transition.

These facts have certain implications for the concept of “universality.” It is generally believed that, insofar as critical exponents near phase transitions are concerned, dimensions and symmetries, not details, are what are important. Our insistence on choosing the lattice action carefully may seem superfluous. In the case of the $O(3)/O(2)$ model the choice of lattice action probably is irrelevant. But the $O(1,2)/O(2) \times Z_2$ model is different. It has no phase transition, and important quantities do depend sensitively on the choice of action.

5 The lattice currents

In the continuum formalism of paper I the form of the conserved currents was deduced from the group invariance of the continuum Lagrangian. The lattice analogs of the currents may

be deduced similarly, from the group invariance of the *lattice Lagrangian*

$$L_{\alpha} = -\frac{1}{2}\beta \sum_{\lambda_{\text{pos}}} \eta_{\lambda} \Delta^2 (\phi_{\alpha}, \phi_{\alpha+\lambda}) . \quad (5.1)$$

Here the summation is over the “positive” values of λ , namely $(1, 0, 0, 0)$, $(0, 1, 0, 0)$, $(0, 0, 1, 0)$ and $(0, 0, 0, 1)$, and the factor η_{λ} assumes the values $-1, 1, 1, 1$ correspondingly. Introduction of η_{λ} and the overall minus sign means that we are working for the moment on a *Minkowski lattice*. The reason for this is to allow the lattice field equations to have nontrivial solutions so that there will be something nontrivial to be conserved!

Reference to eq. (I.4.1), with the index α replaced by the pair ab , shows that group invariance of L_{α} may be stated in the form

$$\begin{aligned} 0 &= \delta L_{\alpha} \\ &= -\frac{1}{4}\beta \sum_{\lambda_{\text{pos}}} \eta_{\lambda} \left[\frac{\partial \Delta^2 (\phi_{\alpha}, \phi_{\alpha+\lambda})}{\partial \phi_{\alpha}^i} Q^i_{ab}(\phi_{\alpha}) + \frac{\partial \Delta^2 (\phi_{\alpha}, \phi_{\alpha+\lambda})}{\partial \phi_{\alpha+\lambda}^i} Q^i_{ab}(\phi_{\alpha+\lambda}) \right] \delta \xi^{ab} . \end{aligned} \quad (5.2)$$

Combining this with the lattice field equations

$$\begin{aligned} 0 &= \frac{\partial S}{\partial \phi_{\alpha}^i} = \frac{\partial}{\partial \phi_{\alpha}^i} \sum_{\alpha'} L_{\alpha'} \\ &= -\frac{1}{2}\beta \sum_{\lambda_{\text{pos}}} \eta_{\lambda} \left[\frac{\partial \Delta^2 (\phi_{\alpha}, \phi_{\alpha+\lambda})}{\partial \phi_{\alpha}^i} + \frac{\partial \Delta^2 (\phi_{\alpha-\lambda}, \phi_{\alpha})}{\partial \phi_{\alpha}^i} \right] \end{aligned} \quad (5.3)$$

and remembering that the $\delta \xi^{ab}$ are arbitrary, one gets

$$\begin{aligned} 0 &= -\frac{1}{2}\beta \sum_{\lambda_{\text{pos}}} \eta_{\lambda} \left[\frac{\partial \Delta^2 (\phi_{\alpha}, \phi_{\alpha+\lambda})}{\partial \phi_{\alpha+\lambda}^i} Q^i_{ab}(\phi_{\alpha+\lambda}) - \frac{\partial \Delta^2 (\phi_{\alpha-\lambda}, \phi_{\alpha})}{\partial \phi_{\alpha}^i} Q^i_{ab}(\phi_{\alpha}) \right] \\ &= \sum_{\lambda_{\text{pos}}} \left[j_{ab}^{\lambda} \left(\alpha + \frac{1}{2}\lambda \right) - j_{ab}^{\lambda} \left(\alpha - \frac{1}{2}\lambda \right) \right] \end{aligned} \quad (5.4)$$

where

$$j_{ab}^{\lambda} \left(\alpha + \frac{1}{2}\lambda \right) \equiv -\frac{1}{2}\beta \eta_{\lambda} \frac{\partial \Delta^2 (\phi_{\alpha}, \phi_{\alpha+\lambda})}{\partial \phi_{\alpha+\lambda}^i} Q^i_{ab}(\phi_{\alpha+\lambda}) . \quad (5.5)$$

Equation (5.4) is the lattice conservation law and expression (5.5) is the lattice current vector.

Passage to the Euclidean lattice is effected by setting $\eta_{\lambda} = 1$ for all λ and writing

$$j_{ab\lambda} \left(\alpha + \frac{1}{2}\lambda \right) = -\frac{1}{2}\beta \frac{\partial \Delta^2 (\phi_{\alpha}, \phi_{\alpha+\lambda})}{\partial \phi_{\alpha+\lambda}^i} Q^i_{ab} (\phi_{\alpha+\lambda}) . \quad (5.6)$$

In paper I an alternative and simpler form (I.4.11 or I.4.17) is given for the currents, based on the action (I.2.5). A Lagrange multiplier can also be introduced here, with the result that expression (5.6) gets replaced by its equivalent

$$j_{ab\lambda} \left(\alpha + \frac{1}{2}\lambda \right) = -\frac{1}{2}\beta \frac{\partial \Delta^2 (\phi_{\alpha}, \phi_{\alpha+\lambda})}{\partial \phi_{\alpha+\lambda}^c} G^c_{abd} \phi_{\alpha+\lambda}^d . \quad (5.7)$$

Making use of the explicit forms (I.3.7) and (I.4.15) one finds

$$j_{ab\lambda} \left(\alpha + \frac{1}{2}\lambda \right) = \beta \frac{\Delta (\phi_{\alpha}, \phi_{\alpha+\lambda})}{\sinh \Delta (\phi_{\alpha}, \phi_{\alpha+\lambda})} (\phi_{a\alpha} \phi_{b\alpha+\lambda} - \phi_{b\alpha} \phi_{a\alpha+\lambda}) \quad (5.8)$$

and, in particular,

$$j_{0i\lambda} \left(\alpha + \frac{1}{2}\lambda \right) = -\beta \frac{\Delta (\phi_{\alpha}, \phi_{\alpha+\lambda})}{\sinh \Delta (\phi_{\alpha}, \phi_{\alpha+\lambda})} (\phi_{\alpha}^0 \phi_{\alpha+\lambda}^i - \phi_{\alpha}^i \phi_{\alpha+\lambda}^0) . \quad (5.9)$$

The lattice Fourier transforms of these currents, namely

$$\tilde{j}_{0i\lambda}(\mathbf{k}) = N^{-2} \sum_{\alpha} j_{0i\lambda} \left(\alpha + \frac{1}{2}\lambda \right) e^{i\mathbf{k} \cdot (\alpha + \frac{1}{2}\lambda)} , \quad (5.10)$$

are to be used in the lattice versions of eq. (I.10.19):

$$\left\langle \tilde{j}_{0i\lambda}(\mathbf{k}) \tilde{j}_{0j\lambda'}(\mathbf{k}') \right\rangle_{\mathbf{k} \rightarrow 0} \xrightarrow{\quad} \beta_R \delta_{ij} \frac{\lambda \cdot \bar{K}(\mathbf{k}) \lambda' \cdot \bar{K}(\mathbf{k})}{\bar{K}^2(\mathbf{k})} \delta_{\mathbf{k}, -\mathbf{k}'}, \quad \lambda \neq \lambda' . \quad (5.11)$$

where

$$\beta_R = \mu_R^2 a^2 . \quad (5.12)$$

Note: Only β_R , *not* μ_R , can be obtained from the computer. If μ_R is to remain finite as $a \rightarrow 0$ then β_R *must vanish in the continuum limit*.

6 The small- β approximation

When the lattice action is chosen in the form (4.2) the lattice version of eq. (I.10.5) may be written

$$\langle A[\phi] \rangle = \frac{\int A[\phi] \exp \left[-\frac{1}{4}\beta \sum_{\alpha, \lambda} \Delta^2 (\phi_{\alpha}, \phi_{\alpha+\lambda}) \right] \prod_{\alpha} \sinh s_{\alpha} ds_{\alpha} d\theta_{\alpha}}{\int \exp \left[-\frac{1}{4}\beta \sum_{\alpha, \lambda} \Delta^2 (\phi_{\alpha}, \phi_{\alpha+\lambda}) \right] \prod_{\alpha} \sinh s_{\alpha} ds_{\alpha} d\theta_{\alpha}} \quad (6.1)$$

where (cf. eq. (I.3.8))

$$\cosh \Delta (\phi_{\alpha}, \phi_{\alpha+\lambda}) = \cosh s_{\alpha} \cosh s_{\alpha+\lambda} - \sinh s_{\alpha} \sinh s_{\alpha+\lambda} \cos (\theta_{\alpha} - \theta_{\alpha+\lambda}) . \quad (6.2)$$

When β is very small the integrals in (6.1) receive important contributions from a vast range of fields. For most of these fields Δ fluctuates over very large values. If the vacuum is fixed, with the lattice averages of ϕ^1 and ϕ^2 held equal to zero, the s_{α} too fluctuate over large values, and eq. (6.2) may be accurately replaced by the approximation

$$\frac{1}{2}e^{\Delta} = \frac{1}{4} \exp (s_{\alpha} + s_{\alpha+\lambda}) [1 - \cos (\theta_{\alpha} - \theta_{\alpha+\lambda})] \quad (6.3)$$

whence

$$\Delta = s_{\alpha} + s_{\alpha+\lambda} + \ln \sin^2 \frac{1}{2} (\theta_{\alpha} - \theta_{\alpha+\lambda}) . \quad (6.4)$$

The corresponding approximation for the expression standing under the integral sign of the denominator in eq. (6.1) is

$$\begin{aligned} & \exp \left[-\frac{1}{4}\beta \sum_{\alpha, \lambda} \Delta^2 (\phi_{\alpha}, \phi_{\alpha+\lambda}) \right] \prod_{\alpha} \sinh s_{\alpha} ds_{\alpha} d\theta_{\alpha} \\ & \xrightarrow{\beta \rightarrow 0} 2^{-N^4} \exp \left\{ \sum_{\alpha} s_{\alpha} - \frac{1}{4}\beta \sum_{\alpha, \lambda} \left[s_{\alpha} + s_{\alpha+\lambda} + \ln \sin^2 \frac{1}{2} (\theta_{\alpha} - \theta_{\alpha+\lambda}) \right]^2 \right\} \prod_{\alpha} ds_{\alpha} d\theta_{\alpha} . \end{aligned} \quad (6.5)$$

The first term in the final exponent represents the effect of the vast area of configuration space that must be probed by the functional integrals as $\beta \rightarrow 0$. The linearity (in the s_{α}) of this term suggests a shift of zero point. Indeed, under the replacement

$$s_{\alpha} = \frac{1}{16\beta} + \frac{\omega_{\alpha}}{\sqrt{\beta}} \quad (6.6)$$

expression (6.5) becomes

$$\begin{aligned} & \left(\frac{1}{2}e^{1/32\beta} \right)^{N^4} \exp \left(-\frac{1}{4} \sum_{\alpha, \lambda} \left\{ (\omega_{\alpha} + \omega_{\alpha+\lambda})^2 + \frac{1}{4} \ln \sin^2 \frac{1}{2} (\theta_{\alpha} - \theta_{\alpha+\lambda}) \right. \right. \\ & \quad \left. \left. + 2\sqrt{\beta} (\omega_{\alpha} + \omega_{\alpha+\lambda}) \ln \sin^2 \frac{1}{2} (\theta_{\alpha} - \theta_{\alpha+\lambda}) \right. \right. \\ & \quad \left. \left. + \beta \left[\ln \sin^2 \frac{1}{2} (\theta_{\alpha} - \theta_{\alpha+\lambda}) \right]^2 \right\} \right) \prod_{\alpha} ds_{\alpha} d\theta_{\alpha} . \end{aligned} \quad (6.7)$$

In the ratio (6.1) the factor in front of the above expression is irrelevant, and if the terms in $\sqrt{\beta}$ and β in the exponent are discarded, the action takes the effective limiting form

$$S_{\omega,\theta} = \frac{1}{4} \sum_{\boldsymbol{\alpha}, \boldsymbol{\lambda}} \left[(\omega_{\boldsymbol{\alpha}} + \omega_{\boldsymbol{\alpha}+\boldsymbol{\lambda}})^2 + \frac{1}{4} \ln \sin^2 \frac{1}{2} (\theta_{\boldsymbol{\alpha}} - \theta_{\boldsymbol{\alpha}+\boldsymbol{\lambda}}) \right], \quad (6.8)$$

which is independent of β ! Even more remarkable, the variables $\omega_{\boldsymbol{\alpha}}$ are governed by Gaussian statistics and decouple from the variables $\theta_{\boldsymbol{\alpha}}$.

The above simple steps appear to give us direct access to the continuum limit. We must, of course, check this, through use of the exact lattice action. The computer results show, in fact, that the approximations embodied in eqs. (6.4) and (6.8) give a good description of the $O(1,2)/O(2) \times Z_2$ model in the small- β limit. For the rest of this section and the next section, therefore, we investigate the implications of the lattice action (6.8).

The ω -part of $S_{\omega,\theta}$ is easily expressed in terms of Fourier components. Proceeding exactly as in the derivation of eq. (2.10) one finds

$$\frac{1}{4} \sum_{\boldsymbol{\alpha}, \boldsymbol{\lambda}} (\omega_{\boldsymbol{\alpha}} + \omega_{\boldsymbol{\alpha}+\boldsymbol{\lambda}})^2 = \frac{1}{2} \sum_{\mathbf{k}} \hat{K}^2(\mathbf{k}) |\tilde{\omega}_{\mathbf{k}}|^2 \quad (6.9)$$

where

$$\hat{K}(\mathbf{k}) = \left(2 \cos \frac{\pi k}{N}, 2 \cos \frac{\pi l}{N}, 2 \cos \frac{\pi m}{N}, 2 \cos \frac{\pi n}{N} \right), \quad (6.10)$$

$$\hat{K}^2(\mathbf{k}) = 16 - \bar{K}^2(\mathbf{k}). \quad (6.11)$$

From this it follows that

$$\langle \tilde{\omega}_{\mathbf{k}} \tilde{\omega}_{\mathbf{k}'} \rangle = \delta_{\mathbf{k}, -\mathbf{k}'} / \hat{K}^2(\mathbf{k}). \quad (6.12)$$

Just as in the case of the massless free field there is a zero mode, but here it corresponds to $\mathbf{k} = \mathbf{k}_s$ where $\mathbf{k}_s = (\frac{1}{2}N, \frac{1}{2}N, \frac{1}{2}N, \frac{1}{2}N)$ rather than to $\mathbf{k} = \mathbf{0}$. On the lattice this mode has the form

$$e^{(2\pi i/N)\mathbf{k}_s \cdot \boldsymbol{\alpha}} = (-1)^{|\boldsymbol{\alpha}|} \quad (6.13)$$

where

$$|\boldsymbol{\alpha}| = |\alpha| + |\beta| + |\gamma| + |\delta|, \quad \boldsymbol{\alpha} = (\alpha, \beta, \gamma, \delta). \quad (6.14)$$

Because of its “spikiness” expression (6.13) will be called the *spike function*. Any multiple of the spike function can be added to $\omega_{\boldsymbol{\alpha}}$ without changing the value of the action $S_{\omega,\theta}$.

The spike mode must be suppressed (i.e., the sum $\sum_{\boldsymbol{\alpha}} (-1)^{|\boldsymbol{\alpha}|} \omega_{\boldsymbol{\alpha}}$ must always be assumed to vanish) for two reasons:

1. The spike function does not respect toroidal periodicity when N is odd and hence does not exist as a zero mode in that case. It is a spurious lattice artifact.
2. If $\sum_{\alpha} (-1)^{|\alpha|} \omega_{\alpha}$ were allowed to drift arbitrarily far from zero then half of the s_{α} of eq. (6.6) could become small enough to render invalid the approximation (6.4) which led to the introduction of the ω_{α} in the first place.

Suppression of the spike mode does not imply that spikiness itself is removed from the theory. Indeed it shows up in the 2-point function $\langle \omega_{\alpha} \omega_{\alpha'} \rangle$. Using double primes on summation signs to indicate that terms with $\mathbf{k} = \mathbf{k}_s$ are to be omitted, and introducing the abbreviation

$$\hat{\mathbf{k}} = \mathbf{k} - \mathbf{k}_s \pmod{N}, \quad \hat{K}(\mathbf{k}) = \bar{K}(\hat{\mathbf{k}}), \quad (6.15)$$

one finds

$$\langle \omega_{\alpha} \omega_{\alpha'} \rangle = N^{-4} \sum''_{\mathbf{k}, \mathbf{k}'} \langle \tilde{\omega}_{\mathbf{k}} \tilde{\omega}_{\mathbf{k}'} \rangle e^{-(2\pi i/N)(\mathbf{k} \cdot \alpha + \mathbf{k}' \cdot \alpha')} = \Omega(\alpha - \alpha') \quad (6.16)$$

where

$$\begin{aligned} \Omega(\alpha) &= N^{-4} \sum''_{\mathbf{k}} \frac{e^{-(2\pi i/N)\mathbf{k} \cdot \alpha}}{\hat{K}^2(\mathbf{k})} \\ &= N^{-4} \sum'_{\hat{\mathbf{k}}} \frac{e^{-(2\pi i/N)(\hat{\mathbf{k}} + \mathbf{k}_s) \cdot \alpha}}{\bar{K}^2(\hat{\mathbf{k}})} = (-1)^{|\alpha|} \Phi(\alpha), \end{aligned} \quad (6.17)$$

$\Phi(\alpha)$ being the free-field 2-point function defined in the Appendix. Since $\Phi(\alpha)$ is a smooth function $\Omega(\alpha)$ is a spiky function. Its spikiness indicates that there are correlations between the ω 's at neighboring sites analogous to spin correlations in antiferromagnetic matter.

Equation (6.17) is strictly valid only when N is even. When N is odd it should be replaced by

$$\Omega(\alpha) = (-1)^{|\alpha|} \Phi_{1/2}(\alpha) \quad (N \text{ odd}) \quad (6.18)$$

where $\Phi_{1/2}$ is defined by the sum (A.2) in the Appendix but with the components of $\mathbf{k}$ running over half-odd-integral values. $\Omega(\alpha)$ is seen to be spiky for both even and odd N . On the computer it is convenient always to work with N even. One can then separate the lattice into *even* and *odd* sites, and this permits efficient computer programming through “vectorization.”

Equations (6.6) and (6.16) lead to an easy derivation of $\langle\phi^0\rangle$ in the small- β limit, patterned on the corresponding derivation (3.14) for the $O(1,1)/Z_2 \times Z_2$ model:

$$\begin{aligned}
\langle\phi^0\rangle &= \langle\cosh s\rangle = \left\langle\cosh\left(\frac{1}{16\beta} + \frac{\omega}{\sqrt{\beta}}\right)\right\rangle \\
&= \cosh\frac{1}{16\beta}\left\langle\cosh\frac{\omega}{\sqrt{\beta}}\right\rangle + \sinh\frac{1}{16\beta}\left\langle\sinh\frac{\omega}{\sqrt{\beta}}\right\rangle \\
&= \frac{1}{2}e^{1/16\beta}\sum_{n=0}^{\infty}\frac{1}{(2\beta)^nn!}\langle\omega^2\rangle^n = \frac{1}{2}e^{[\frac{1}{8}+\Omega(0)]/2\beta} \\
&\xrightarrow{N\rightarrow\infty} \frac{1}{2}e^{.28/2\beta}.
\end{aligned} \tag{6.19}$$

The last line follows from

$$\Omega(0) = \Phi(0) = F(N) \xrightarrow{N\rightarrow\infty} .1549\dots \tag{6.20}$$

(see eqs. (6.17) and (A.5)). $\langle\phi^0\rangle$ here, like $\langle\phi^0\rangle$ for the $O(1,1)/Z_2 \times Z_2$ model, has an essential singularity as $\beta \rightarrow 0$, which makes it difficult to evaluate on the computer. It is, in fact, doubly hard to compute for the following reason: In the small- β limit a histogram of the accumulated values that s assumes over the lattice has a Gaussian form of width $\sqrt{\Omega(0)/\beta}$ peaked at $1/16\beta = .0625/\beta$. (See section 8, Figs. 2 and 3, for numerical confirmation of this.) But the most important contributions to $\langle\phi^0\rangle$ come from values of s near $.14/\beta$, which is way out in the tail of the Gaussian distribution. The computed value of $\langle\phi^0\rangle$ is extremely sensitive to the tail of the histogram, and reliable values for it simply cannot be obtained. Consequently, eqs. (I.8.20) to (I.8.23), which are based on the fields ϕ^a , do not provide a useful route to the renormalized Planck mass or, on the computer, to the constant β_R of eq. (5.12).

7 The fields σ_i and the θ -part of $S_{\omega,\theta}$

We have found that the Riemann normal variables σ^i of eq. (I.6.15) *do* yield reliable 2-point functions on the computer. In the small- β limit the renormalization constant Z_σ of eq. (I.10.15) becomes

$$Z_\sigma = \frac{1}{2}\left\langle\left(1 + \frac{s \cosh s}{\sinh s}\right)\right\rangle \xrightarrow{\beta\rightarrow 0} \frac{1}{32\beta}, \tag{7.1}$$

and the renormalized fields (I.10.17) are given by

$$\sigma_R^i = 32\beta\sigma^i. \quad (7.2)$$

The renormalized 2-point functions therefore have the small- β limits

$$\begin{aligned} \langle \sigma_R^1 \boldsymbol{\alpha} \sigma_R^1 \boldsymbol{\alpha}' \rangle &= (32\beta)^2 \langle s_{\boldsymbol{\alpha}} s_{\boldsymbol{\alpha}'} \rangle \langle \cos \theta_{\boldsymbol{\alpha}} \cos \theta_{\boldsymbol{\alpha}'} \rangle \\ &= (32\beta)^2 \left\langle \left(\frac{1}{16\beta} + \frac{\omega_{\boldsymbol{\alpha}}}{\sqrt{\beta}} \right) \left(\frac{1}{16\beta} + \frac{\omega_{\boldsymbol{\alpha}'}}{\sqrt{\beta}} \right) \right\rangle \langle \cos \theta_{\boldsymbol{\alpha}} \cos \theta_{\boldsymbol{\alpha}'} \rangle \\ &\xrightarrow{\beta \rightarrow 0} 4 \langle \cos \theta_{\boldsymbol{\alpha}} \cos \theta_{\boldsymbol{\alpha}'} \rangle \end{aligned} \quad (7.3)$$

and, similarly,

$$\langle \sigma_R^1 \boldsymbol{\alpha} \sigma_R^2 \boldsymbol{\alpha}' \rangle \xrightarrow{\beta \rightarrow 0} 4 \langle \cos \theta_{\boldsymbol{\alpha}} \sin \theta_{\boldsymbol{\alpha}'} \rangle, \quad (7.4)$$

$$\langle \sigma_R^2 \boldsymbol{\alpha} \sigma_R^2 \boldsymbol{\alpha}' \rangle \xrightarrow{\beta \rightarrow 0} 4 \langle \sin \theta_{\boldsymbol{\alpha}} \sin \theta_{\boldsymbol{\alpha}'} \rangle. \quad (7.5)$$

Owing to the $O(2)$ invariance of the vacuum one expects expression (7.4) to vanish and expressions (7.3) and (7.5) to be equal, so that

$$\langle \sigma_R^i \boldsymbol{\alpha} \sigma_R^j \boldsymbol{\alpha}' \rangle \xrightarrow{\beta \rightarrow 0} \delta_{ij} \Theta(\boldsymbol{\alpha} - \boldsymbol{\alpha}') \quad (7.6)$$

where

$$\begin{aligned} \Theta(\boldsymbol{\alpha} - \boldsymbol{\alpha}') &= 4 \langle \cos \theta_{\boldsymbol{\alpha}} \cos \theta_{\boldsymbol{\alpha}'} \rangle = 4 \langle \sin \theta_{\boldsymbol{\alpha}} \sin \theta_{\boldsymbol{\alpha}'} \rangle \\ &= 2 \langle (\cos \theta_{\boldsymbol{\alpha}} \cos \theta_{\boldsymbol{\alpha}'} + \sin \theta_{\boldsymbol{\alpha}} \sin \theta_{\boldsymbol{\alpha}'} \rangle = 2 \langle \cos(\theta_{\boldsymbol{\alpha}} - \theta_{\boldsymbol{\alpha}'} \rangle. \end{aligned} \quad (7.7)$$

The question of the existence of a continuum limit for the $O(1,2)/O(2) \times Z_2$ model is seen to be determined entirely by the θ -part of the action $S_{\omega,\theta}$. The reader should note that the above limiting forms for the renormalized 2-point functions are all independent of β .

The θ -part of $S_{\omega,\theta}$ gives rise to the following unusual average:

$$\langle A[\theta] \rangle = \frac{\int d\theta A[\theta] \Pi_{\boldsymbol{\alpha}, \boldsymbol{\lambda}_{\text{pos}}} \left| \sin \frac{1}{2} (\theta_{\boldsymbol{\alpha}} - \theta_{\boldsymbol{\alpha}+\boldsymbol{\lambda}}) \right|^{-1/4}}{\int d\theta \Pi_{\boldsymbol{\alpha}, \boldsymbol{\lambda}_{\text{pos}}} \left| \sin \frac{1}{2} (\theta_{\boldsymbol{\alpha}} - \theta_{\boldsymbol{\alpha}+\boldsymbol{\lambda}}) \right|^{-1/4}}, \quad (7.8)$$

$$\int d\theta \equiv \prod_{\boldsymbol{\alpha}} \int_0^{2\pi} d\theta_{\boldsymbol{\alpha}}. \quad (7.9)$$

Note that the integrands become singular when the cross-link differences $\Delta\theta = \theta_{\boldsymbol{\alpha}} - \theta_{\boldsymbol{\alpha}+\boldsymbol{\lambda}}$ vanish. One therefore expects histograms of the $\Delta\theta$'s to be strongly peaked around zero. This is confirmed by the computer results. (See Fig. 1.) The singularity of the integrands

stems from the fact that the action $S_{\omega,\theta}$ is unbounded from below (see eq. (6.8)). The question immediately arises why the Monte Carlo procedure *works* when $S_{\omega,\theta}$ is used. It is shown in the Appendix that the singularities to which $S_{\omega,\theta}$ gives rise are just soft enough for the functional integrals to exist.

Another unusual feature of the average (7.8) is that its weight, or “measure,” in addition to being invariant under the obvious $O(2)$ transformations

$$\theta_{\alpha} \rightarrow \theta_{\alpha} + \text{constant}, \quad \theta_{\alpha} \rightarrow -\theta_{\alpha}, \quad (7.10)$$

is invariant as well under a set of nonlinear transformations having the infinitesimal form

$$\delta\theta_{\alpha} = \epsilon_1 \cos \theta_{\alpha} + \epsilon_2 \sin \theta_{\alpha}. \quad (7.11)$$

The existence of the latter invariance, which is demonstrated in the Appendix, derives directly from the $O(1,2)$ invariance of the measure of the average (6.1). The transformation (7.11) is easily recognized as an expression of the well known “headlight effect” associated with Lorentz boosts.

When using the “exact” action (4.2) one must program the computer to execute $O(1,2)$ boosts at the end of each Monte Carlo sweep in order to keep the lattice averages of ϕ^1 and ϕ^2 equal to zero and hence to keep the vacuum state from drifting. When using the θ -part of the action $S_{\omega,\theta}$ one must, for the same reason, program the computer to execute transformations of the form (7.11) after each sweep. In this case the vacuum is held fixed if the constraints

$$\sum_{\alpha} \cos \theta_{\alpha} = 0, \quad \sum_{\alpha} \sin \theta_{\alpha} = 0, \quad (7.12)$$

which express the $O(2)$ invariance of the vacuum, are maintained. At the end of each sweep the θ_{α} will be fairly randomly distributed from 0 to 2π (if the lattice is big enough) and will approximately satisfy the equations

$$N^{-4} \sum_{\alpha} \cos^2 \theta_{\alpha} = N^{-4} \sum_{\alpha} \sin^2 \theta_{\alpha} = \frac{1}{2}, \quad N^{-4} \sum_{\alpha} \sin \theta_{\alpha} \cos \theta_{\alpha} = 0. \quad (7.13)$$

Moreover, eqs. (7.12) will be violated only slightly. Defining

$$N^{-4} \sum_{\alpha} \cos \theta_{\alpha} \equiv C \ll 1, \quad N^{-4} \sum_{\alpha} \sin \theta_{\alpha} \equiv S \ll 1, \quad (7.14)$$

one easily sees that the constraints will, to good accuracy, be reestablished by the transformation (7.11) if ϵ_1 and ϵ_2 are chosen to be

$$\epsilon_1 = -2S, \quad \epsilon_2 = 2C. \quad (7.15)$$

This choice has been found to work well on the computer.

We close this section by noting that, in the small- β limit, not only the σ 2-point functions (7.6) but also the current 2-point functions (5.11) and (5.12) are determined entirely by the θ -part of the action $S_{\omega,\theta}$. Referring to eqs. (5.9), (6.4) and (6.6), one easily obtains the limiting forms

$$j_{01}\lambda \left(\alpha + \frac{1}{2}\lambda \right) \xrightarrow{\beta \rightarrow 0} -\frac{1}{16} \frac{\cos \theta_{\alpha+\lambda} - \cos \theta_{\alpha}}{\sin^2 \frac{1}{2} (\theta_{\alpha+\lambda} - \theta_{\alpha})} = \frac{1}{8} \frac{\sin \frac{1}{2} (\theta_{\alpha+\lambda} + \theta_{\alpha})}{\sin \frac{1}{2} (\theta_{\alpha+\lambda} - \theta_{\alpha})}, \quad (7.16)$$

$$j_{02}\lambda \left(\alpha + \frac{1}{2}\lambda \right) \xrightarrow{\beta \rightarrow 0} -\frac{1}{16} \frac{\sin \theta_{\alpha+\lambda} - \sin \theta_{\alpha}}{\sin^2 \frac{1}{2} (\theta_{\alpha+\lambda} - \theta_{\alpha})} = -\frac{1}{8} \frac{\cos \frac{1}{2} (\theta_{\alpha+\lambda} + \theta_{\alpha})}{\sin \frac{1}{2} (\theta_{\alpha+\lambda} - \theta_{\alpha})}, \quad (7.17)$$

which are independent of the ω_{α} .

8 Computer results

If one is to use the limiting action $S_{\omega,\theta}$ with confidence, one must check how well the results obtained with the full action (4.2) tend, when β is small, toward those obtained with $S_{\omega,\theta}$. This immediately raises the question: How small is *small*?

Consider eq. (7.3). If β is not set equal to zero this equation implies

$$\langle \sigma_{R\alpha}^1 \sigma_{R\alpha'}^1 \rangle = \left[4 + (32)^2 \beta \Omega(\alpha - \alpha') \right] \langle \cos \theta_{\alpha} \cos \theta_{\alpha'} \rangle, \quad (8.1)$$

and one sees that the second term in the brackets cannot be ignored unless

$$\beta \ll 4(32)^{-2}/\Omega(0) = .025. \quad (8.2)$$

Such small values for β have the potential of severely taxing the ability of the computer. In early runs attempts were made to compute $\langle \phi_{R\alpha}^i \phi_{R\alpha'}^j \rangle$ at $\beta \lesssim .002$, without success. The cause of the failure was the same as that which makes the computation of $\langle \phi^0 \rangle$ impractical, as explained at the end of section 6. On the computer the difficulty can masquerade as *critical slowing down*, causing large autocorrelation intervals, drifting averages, etc. But in fact critical slowing down has nothing to do with it. Computations of $\langle \sigma_{R\alpha}^i \sigma_{R\alpha'}^j \rangle$ have turned out to generate autocorrelation intervals of less than 20 sweeps, even for β 's as small as 10^{-4} . Moreover, the results have been found to be both reliable and accurate.

A simple measure of the validity of the small- β approximation is the quantity

$$\left\langle \frac{|\Delta' - \Delta|}{\Delta} \right\rangle, \quad (8.3)$$

where Δ is the exact cross-link geodetic distance, Δ' is the approximation to it given by eq. (6.4), and the average is over links and sweeps. At $\beta = 10^{-3}$ expression (8.3) is found to be already less than 10^{-7} , so the small- β approximation is indeed a good one.

More detailed measures of the quality of the small- β approximation are provided by histograms of the s_{α} and of the cross-link differences $\Delta\theta = \theta_{\alpha} - \theta_{\alpha+\lambda}$. Figure 1 shows the $\Delta\theta$ histograms for both the exact lattice action (4.2), at $\beta = 10^{-4}$ and $N = 10$, and the θ -part of the approximate action $S_{\omega,\theta}$, at $N = 10$. The two curves, which were compiled by accumulating all cross-link differences for 60,000 sweeps, are indistinguishable. Figures 2 and 3 show the s_{α} histograms for the exact action, at $\beta = 10^{-3}$ and 10^{-4} with $N = 10$, superimposed upon the theoretical Gaussian curve derived from eq. (6.6) and the ω -part of the action $S_{\omega,\theta}$. Again the agreement is excellent.

It should be stated that during the runs at $\beta \leq 10^{-3}$ the spike mode (see section 6) began to appear spontaneously and randomly, in the fields generated by the Monte Carlo procedure. At these values of β this spurious mode was forcibly removed from the field at the end of each sweep after the vacuum-fixing boost was applied. As remarked in section 6, suppression of the spike mode does not remove spikiness itself from the theory. (See the discussion of the σ 2-point function below.)

It should also be stated that during the small- β runs the vacuum-fixing boosts applied at the end of each sweep were chosen so as to enforce the conditions (7.12) rather than the conditions

$$\sum_{\alpha} \phi^1_{\alpha} = 0, \quad \sum_{\alpha} \phi^2_{\alpha} = 0. \quad (8.4)$$

Because of the huge values assumed by the ϕ^i_{α} ($\sim 10^{27 \pm 10}$ when $\beta = 10^{-3}$ and $\sim 10^{273 \pm 33}$ when $\beta = 10^{-4}$) enforcement of (8.4) is impractical at these β 's. We *could* have imposed the alternative conditions

$$\sum_{\alpha} \sigma^1_{\alpha} = 0, \quad \sum_{\alpha} \sigma^2_{\alpha} = 0, \quad (8.5)$$

but we felt that, to make comparisons, it was best to uniformly impose conditions (7.12), which are the only ones available when the action $S_{\omega,\theta}$ is used. It turns out that enforcement of (7.12) causes conditions (8.5) also to be satisfied to better than .03% accuracy provided N is big enough (≥ 10) so that a “snapshot” of the lattice after each boost provides a fair sampling of field values.

The results displayed in Figs. 1, 2 and 3 give us confidence in proceeding to the computation of β_R . We discuss first the determination of β_R based on the lattice version of

eq. (I.10.16):

$$\langle \tilde{\sigma}_{R\mathbf{k}}^i \tilde{\sigma}_{R\mathbf{k}'}^j \rangle = \frac{\delta_{ij} \delta_{\mathbf{k}, -\mathbf{k}'}}{\beta_R \bar{K}^2(\mathbf{k}) + \dots} . \quad (8.6)$$

Here $\tilde{\sigma}_{R\mathbf{k}}^i$ is the lattice Fourier transform of the field $\sigma_{R\alpha}^i = Z_\sigma^{-1} \sigma_\alpha^i$. Note that the determination of β_R requires a computation of the renormalization constant Z_σ (eqs. (I.10.15) and (7.1)) as well as the σ 2-point function. According to eq. (8.6) β_R is given by the intercept (at $\mathbf{k} = 0$) of the function $2/\bar{K}^2(\mathbf{k}) \langle \tilde{\sigma}_{R\mathbf{k}}^i \tilde{\sigma}_{R\mathbf{k}}^{i*} \rangle$. Figure 4 shows plots of this function for $N = 10$ and various values of β , as well as of the corresponding function for the action $S_{\omega, \theta}$ (eqs. (7.6) and (8.7)). At the smaller values of β and at low momenta the curves fall right on top of one another. The differences between the curves at higher momenta is explained by the spikiness of the function $\langle \sigma_{R\alpha}^i \sigma_{R\alpha'}^i \rangle$ arising from $\Omega(\alpha - \alpha')$ in eq. (8.1). The spikiness is a short-wavelength phenomenon that is picked up by the Fourier transforms. It goes away as $\beta \rightarrow 0$.

Figure 5 shows a plot of β_R vs. β as determined from the intercepts of the curves shown in Fig. 4. It is on this plot that we base our conclusion that the quantized $O(1, 2)/O(2) \times Z_2$ sigma model has no continuum limit in four dimensions. The key fact is that β_R *vanishes nowhere, not even at $\beta = 0$* . In view of the definition of β_R (eq. (5.12)) this implies that the renormalized Planck mass μ_R must become infinite in the continuum limit $a \rightarrow 0$.

Figure 6 shows a plot of β_R vs. N for the action $S_{\omega, \theta}$, i.e., for $\beta = 0$. It is evident that β_R tends to a constant value as N increases past 10. Its value on an *infinite* lattice is therefore effectively known, and one can pass to the continuum limit $a \rightarrow 0$ without worrying that the size of the “universe” (the lattice 4-torus) is simultaneously collapsing to zero. The nonvanishing of β_R , and the blowup of μ_R , is *not* an artifact of a vanishing universe.

If a similar result (infinite μ_R) is eventually found in conventional quantum gravity we shall be forced to conclude that the theory is not viable, because the classical theory of Einstein cannot emerge from it as a low-energy limit. In the case of the $O(1, 2)/O(2) \times Z_2$ model the blowup of μ_R implies that there can be no low-energy “classical” regime in which the physics is described by an action functional having the form of the first term on the right side of eq. (I.8.18). It is in this sense that we say that the quantized $O(1, 2)/O(2) \times Z_2$ model has no continuum limit.

It may occasionally be useful to adopt an alternative viewpoint by saying that the continuum limit exists but is trivial. However, this viewpoint can be misleading on two accounts:

1. It reinforces the current folklore which claims that all scalar field theories in four dimensions are trivial. The claim is suspect because it *is* just folklore. No valid

argument exists that would have given us knowledge *a priori* that μ_R must blow up in the continuum limit. Each scalar theory must be investigated on its own. For example, despite the amount of research that has been done on the $O(3)/O(2)$ model, it is still unknown whether a continuum limit exists for it when the action (4.2) is used. If β_R does vanish anywhere for this model one presumes that it will do so at the phase-transition point $\beta = \beta_c$, but no one knows.

2. While it is true that the $O(1,2)/O(2) \times Z_2$ model becomes trivial in the continuum limit, in the sense that the renormalized “coupling constant” μ_R^{-2} vanishes, it is also true that in this limit the model is no longer $O(1,2)/O(2) \times Z_2$. The configuration space becomes flat and the invariance group consists of the isometries of the plane, not the elements of $O(1,2)$. Therefore, although the continuum limit “exists,” the model does not.

We remark that the continuum limit may properly be regarded as located at $\beta = 0$, not only because the naïve continuum limit is located there (with the bare Planck mass μ held at a fixed finite value) but also because the lattice specific heat diverges there, making $\beta = 0$ a critical point of the theory. This may be seen by introducing the “partition function”

$$Z(\beta) = \int e^{-\beta E[\phi]} \mu[\phi] d\phi \quad (8.7)$$

and noting that eq. (3.20) is equivalent to

$$c_L = N^{-4} \left[\frac{1}{Z} \frac{d^2 Z}{d\beta^2} - \frac{1}{Z^2} \left(\frac{dZ}{d\beta} \right)^2 \right]. \quad (8.8)$$

In the small- β limit the partition function is dominated by the first factor in expression (6.7), whence

$$Z = \text{const.} \times e^{N^4/32\beta}. \quad (8.9)$$

This immediately yields

$$c_L = \text{const.} \times \beta^{-3}, \quad (8.10)$$

which diverges at $\beta = 0$. The critical exponent, -3 , in eq. (8.10) has been confirmed by direct computation of (3.20) for the exact action (4.2). Note that this critical exponent differs from that of the massless free field (eq. (3.21)).

The “triviality” of the continuum limit of the $O(1,2)/O(2) \times Z_2$ model, which is entirely due to the nonvanishing of β_R , implies nothing about the shape of the $\beta = 0$ curve in Fig. 4.

Since this curve is plotted effectively as a function of p^2/μ_R^2 , and since μ_R^2 diverges, finite physical values of p^2 are all located at the left-hand intercept. It is therefore quite remarkable that this curve is nevertheless very nearly a straight horizontal line. Such a result was by no means obvious *a priori*. Suppose one were to present a mathematician with eq. (7.8) without telling him where it came from. How could he possibly know in advance that the average (7.7), defined by (7.8), would be very nearly the 2-point function for a pair of free fields?

There is a consistency check on this curious result. Once one knows that the average (7.7) is very nearly proportional to the 2-point function $\Phi(\alpha - \alpha')$ for the free field, one may use the proportionality constant to define β_R at $\beta = 0$:

$$\Theta(\alpha - \alpha') \approx \beta_R^{-1} \Phi(\alpha - \alpha'). \quad (8.11)$$

But from eq. (7.7) it is obvious that $\Theta(0) = 2$. Moreover

$$\Phi(0) = F(N) \xrightarrow{N \rightarrow \infty} .1549, \quad (8.12)$$

whence it must follow that

$$\beta_R \approx \frac{1}{2} F(N) \xrightarrow{N \rightarrow \infty} .0775, \quad (8.13)$$

which agrees very well with Fig. 6.

It is useful to sketch the procedure that we should have had to adopt if things had turned out differently and β_R were to vanish for some value of β . To begin with we should have tried to match the σ 2-point function of the continuum theory to an Ansatz of the form

$$\langle \tilde{\sigma}_R^i(p) \tilde{\sigma}_R^j(p') \rangle = \frac{\delta_{ij} \delta(p + p')}{\mu_R^2 p^2 + (\alpha/\mu_R^2) p^6 \ln(p^2/\lambda\mu_R^2)} \quad (8.14)$$

or some variant thereof. Here α and λ are dimensionless fitting parameters independent of μ_R . Equation (8.14) would be a universal formula, with μ_R merely setting the scale.

The lattice analog of (8.14) is

$$\langle \tilde{\sigma}_{R\mathbf{k}}^i \tilde{\sigma}_{R\mathbf{k}'}^j \rangle = \frac{\delta_{ij} \delta_{\mathbf{k}, -\mathbf{k}'}}{\beta_R \bar{K}^2 + (\alpha/\beta_R) \bar{K}^6 \ln(\bar{K}^2/\lambda\beta_R)}. \quad (8.15)$$

This formula becomes meaningless when β_R vanishes, and one might therefore be tempted to conclude that, since the average (7.7) is independent of β , it was obvious, as soon as eqs. (7.6) and (7.7) were written down, that β_R cannot vanish. But this would be too hasty a conclusion. Every finite lattice has associated with it an “infrared” mass

$$\mu' = 1/L = 1/Na. \quad (8.16)$$

The corresponding lattice quantity is

$$\beta' = \mu'^2 a^2 = N^{-2}, \quad (8.17)$$

which, because it remains finite as a goes to zero, could quite possibly mask β_R in the limit. If the real β_R had turned out to vanish then one would have found that the *effective* β_R defined by eq. (8.6) was proportional to N^{-2} . One might have regarded any hope for such a result as foredoomed, in view of the insensitivity of most averages to N , once N is bigger than 6 or 8. But eq. (7.8) defines an unusual kind of average, and we had no advance knowledge of its properties.

We turn finally to the determination of β_R from the current-current average (5.11). Because of large scatter in the individual values of $\tilde{j}_{0i}\boldsymbol{\lambda}(\mathbf{k})\tilde{j}_{0i}\boldsymbol{\lambda}'(k)^*$ we found that it was not possible to use eq. (5.11) at values of β below 10^{-2} . But down to that value the agreement between the values of β_R obtained from the σ 2-point function and those obtained from (5.11) is good. Indeed, Fig. 7 shows that the agreement is remarkably good. Because the determination of β_R from (5.11) avoids computation of the renormalization constant Z_σ , this good agreement is far from trivial. It is a convincing demonstration of the consistency of the formal arguments presented in paper I. It makes one believe that there is something to quantum field theory after all!

In closing we note yet another consistency check on the formalism. Equations (I.9.2), (I.9.3), (I.9.4) and (I.9.7) together imply

$$\langle \text{vac} | T \left(\sigma^i(x) j_{0j}^\mu(x') \right) | \text{vac} \rangle = \frac{\delta_{ij} Z_\sigma}{(2\pi)^4} \int \frac{p^\mu}{p^2} e^{ip \cdot (x-x')} d^4 p. \quad (8.18)$$

Replacing σ^i by σ_R^i , passing to Euclidean space and taking Fourier transforms, we get

$$\langle \tilde{\sigma}_R^i(p) \tilde{j}_{0j}^\mu(p) \rangle = i \delta_{ij} \frac{p^\mu}{p^2} \delta(p + p'). \quad (8.19)$$

The lattice version of this equation yields

$$\left| \langle \tilde{\sigma}_{R\mathbf{k}}^i \tilde{j}_{0i}\boldsymbol{\lambda}(\mathbf{k})^* \rangle \right| = 2 \frac{\boldsymbol{\lambda} \cdot \bar{K}(\mathbf{k})}{\bar{K}^2(\mathbf{k})}, \quad (8.20)$$

which is a universal function, the same for all values of β . Equation (8.20) has been checked at $N = 4$ for all values of $\mathbf{k}$ and $\boldsymbol{\lambda}$ and for many values of β . We have found it to be satisfied to 5% accuracy for values of β down to .05, and to 20% accuracy at $\beta = .02$. At lower values of β large scatter makes checking impossible. Although eq. (8.20) gives no information about the continuum limit, it is nevertheless a remarkable equation. Its left-hand side depends on

Z_σ and β ; its right-hand side depends on neither. Its “experimental” verification gives us one more reason to believe that we have done the right things.

Appendix

Estimating $F(N)$

To estimate $F(N)$ use the approximation (2.15). The exact equation for the 2-point function is

$$\langle \phi_{\boldsymbol{\alpha}} \phi_{\boldsymbol{\alpha}'} \rangle = \frac{1}{\beta} \Phi(\boldsymbol{\alpha} - \boldsymbol{\alpha}') \quad (\text{A.1})$$

where (cf. eq. (2.14))

$$\Phi(\boldsymbol{\alpha}) = N^{-4} \sum_{\mathbf{k}}' \frac{e^{-(2\pi i/N)\mathbf{k} \cdot \boldsymbol{\alpha}}}{\bar{K}^2(\mathbf{k})}. \quad (\text{A.2})$$

Evidently

$$\Phi(\mathbf{0}) = F(N), \quad (\text{A.3})$$

and, from eq. (2.15),

$$\Phi(\boldsymbol{\lambda}) \approx \frac{1}{4\pi^2 \boldsymbol{\lambda}^2} = \frac{1}{4\pi^2} = .025 \dots \text{ for all } \boldsymbol{\lambda}. \quad (\text{A.4})$$

Now use the fact that Φ satisfies a simple equation involving the lattice Laplacian:

$$\begin{aligned} & \frac{1}{2} \sum_{\boldsymbol{\lambda}} [-\Phi(\boldsymbol{\alpha} + \boldsymbol{\lambda}) + 2\Phi(\boldsymbol{\alpha}) - \Phi(\boldsymbol{\alpha} - \boldsymbol{\lambda})] \\ &= \frac{1}{2} N^{-4} \sum_{\boldsymbol{\lambda}} \sum_{\mathbf{k}}' \left[-e^{-(2\pi i/N)\mathbf{k} \cdot (\boldsymbol{\alpha} + \boldsymbol{\lambda})} + 2e^{-(2\pi i/N)\mathbf{k} \cdot \boldsymbol{\alpha}} - e^{-(2\pi i/N)\mathbf{k} \cdot (\boldsymbol{\alpha} - \boldsymbol{\lambda})} \right] / \bar{K}^2(\mathbf{k}) \\ &= N^{-4} \sum_{\mathbf{k}}' e^{-(2\pi i/N)\mathbf{k} \cdot \boldsymbol{\alpha}} = \delta_{\boldsymbol{\alpha}\mathbf{0}} - N^{-4} \end{aligned} \quad (\text{A.5})$$

in which eq. (2.13) is used in passing to the last line. Setting $\boldsymbol{\alpha} = \mathbf{0}$ in (A.5) and remembering that $\boldsymbol{\lambda}$ ranges over eight different values, get

$$1 - N^{-4} = 8 [\Phi(\mathbf{0}) - \Phi(\boldsymbol{\lambda})] \approx 8 [F(N) - .025],$$

whence

$$F(N) \approx .025 + \frac{1}{8} (1 - N^{-4}) \xrightarrow{N \rightarrow \infty} .15. \quad (\text{A.6})$$

Invariance of the measure of the average (7.8)

The measure may be written in the form

$$\prod_{\boldsymbol{\alpha}} d\theta_{\boldsymbol{\alpha}} \prod_{\boldsymbol{\lambda}} \left[\sin^2 \frac{1}{2} (\theta_{\boldsymbol{\alpha}} - \theta_{\boldsymbol{\alpha}+\boldsymbol{\lambda}}) \right]^{-1/16}. \quad (\text{A.7})$$

Setting $\theta'_{\boldsymbol{\alpha}} = \theta_{\boldsymbol{\alpha}} + \delta\theta_{\boldsymbol{\alpha}}$ one finds for the change in $d\theta_{\boldsymbol{\alpha}}$ under the infinitesimal transformation (7.11)

$$\begin{aligned} \delta d\theta_{\boldsymbol{\alpha}} &= d\theta'_{\boldsymbol{\alpha}} - d\theta_{\boldsymbol{\alpha}} = [(\partial\theta'_{\boldsymbol{\alpha}}/\partial\theta_{\boldsymbol{\alpha}}) - 1] d\theta_{\boldsymbol{\alpha}} = (\partial\delta\theta_{\boldsymbol{\alpha}}/\partial\theta_{\boldsymbol{\alpha}}) d\theta_{\boldsymbol{\alpha}} \\ &= (-\epsilon_1 \sin \theta_{\boldsymbol{\alpha}} + \epsilon_2 \cos \theta_{\boldsymbol{\alpha}}) d\theta_{\boldsymbol{\alpha}} \end{aligned} \quad (\text{A.8})$$

and hence

$$\delta \prod_{\boldsymbol{\alpha}} d\theta_{\boldsymbol{\alpha}} = \left(\prod_{\boldsymbol{\alpha}} d\theta_{\boldsymbol{\alpha}} \right) \sum_{\boldsymbol{\alpha}} (-\epsilon_1 \sin \theta_{\boldsymbol{\alpha}} + \epsilon_2 \cos \theta_{\boldsymbol{\alpha}}). \quad (\text{A.9})$$

Moreover,

$$\begin{aligned} &\delta \left[\sin^2 \frac{1}{2} (\theta_{\boldsymbol{\alpha}} - \theta_{\boldsymbol{\alpha}+\boldsymbol{\lambda}}) \right]^{-1/16} \\ &= -\frac{1}{16} \left[\sin^2 \frac{1}{2} (\theta_{\boldsymbol{\alpha}} + \theta_{\boldsymbol{\alpha}+\boldsymbol{\lambda}}) \right]^{-1/16} \frac{\cos \frac{1}{2} (\theta_{\boldsymbol{\alpha}} - \theta_{\boldsymbol{\alpha}+\boldsymbol{\lambda}})}{\sin \frac{1}{2} (\theta_{\boldsymbol{\alpha}} - \theta_{\boldsymbol{\alpha}+\boldsymbol{\lambda}})} (\delta\theta_{\boldsymbol{\alpha}} - \delta\theta_{\boldsymbol{\alpha}+\boldsymbol{\lambda}}) \\ &= -\frac{1}{16} \left[\sin^2 \frac{1}{2} (\theta_{\boldsymbol{\alpha}} + \theta_{\boldsymbol{\alpha}+\boldsymbol{\lambda}}) \right]^{-1/16} \left[-2\epsilon_1 \cos \frac{1}{2} (\theta_{\boldsymbol{\alpha}} - \theta_{\boldsymbol{\alpha}+\boldsymbol{\lambda}}) \sin \frac{1}{2} (\theta_{\boldsymbol{\alpha}} + \theta_{\boldsymbol{\alpha}+\boldsymbol{\lambda}}) \right. \\ &\quad \left. + 2\epsilon_2 \cos \frac{1}{2} (\theta_{\boldsymbol{\alpha}} - \theta_{\boldsymbol{\alpha}+\boldsymbol{\lambda}}) \cos \frac{1}{2} (\theta_{\boldsymbol{\alpha}} + \theta_{\boldsymbol{\alpha}+\boldsymbol{\lambda}}) \right], \end{aligned} \quad (\text{A.10})$$

the trigonometric identities

$$\left. \begin{aligned} \cos x - \cos y &= -2 \sin \frac{1}{2}(x - y) \sin \frac{1}{2}(x + y) \\ \sin x - \sin y &= 2 \sin \frac{1}{2}(x - y) \cos \frac{1}{2}(x + y) \end{aligned} \right\} \quad (\text{A.11})$$

being used in passing to the final form. The complementary identities

$$\left. \begin{aligned} \cos x + \cos y &= 2 \cos \frac{1}{2}(x - y) \cos \frac{1}{2}(x + y) \\ \sin x + \sin y &= 2 \cos \frac{1}{2}(x - y) \sin \frac{1}{2}(x + y) \end{aligned} \right\} \quad (\text{A.12})$$

permit expression (A.10) to be further simplified, and one sees that, under (7.11), the measure (A.7) gets multiplied by

$$\sum_{\alpha} \left\{ -\epsilon_1 \sin \theta_{\alpha} + \epsilon_2 \cos \theta_{\alpha} - \frac{1}{16} \sum_{\lambda} \left[-\epsilon_1 (\sin \theta_{\alpha} + \sin \theta_{\alpha+\lambda}) + \epsilon_2 (\cos \theta_{\alpha} + \cos \theta_{\alpha+\lambda}) \right] \right\}. \quad (\text{A.13})$$

But this vanishes by virtue of the fact that λ ranges over 8 values per site. It follows that the measure is invariant under (7.11).

Proof of the existence of the functional integrals in (7.8)

The integrands become singular when two or more θ_{α} 's approach simultaneously a common value $\bar{\theta}$. Consider therefore a rectangular subvolume of the lattice containing $JKLM$ sites, where J, K, L, M are integers between 1 and N , at least one of which is greater than 1. The number of links in this subvolume is $4JKLM - JKL - JKM - JLM - KLM$. Replace the integration variables θ_{α} attached to the $JKLM$ sites by $\bar{\theta}, \Delta\theta$ and $JKLM - 2$ angular variables in $(JKLM - 1)$ -dimensional Euclidean space. The variable $\Delta\theta$ is the maximum distance of any of the θ_{α} 's from the common value $\bar{\theta}$ and is the critical variable for determining the convergence of the associated subintegration. At small values of $\Delta\theta$ the $\Delta\theta$ subintegration goes like

$$\begin{aligned} & \int_0 (\Delta\theta)^{-\frac{1}{4}(4JKLM - JKL - JKM - JLM - KLM)} (\Delta\theta)^{JKLM-2} d(\Delta\theta) \\ &= \int_0 (\Delta\theta)^{\frac{1}{4}(JKL + JKM + JLM + KLM) - 2} d(\Delta\theta). \end{aligned} \quad (\text{A.14})$$

But $JKL + JKM + JLM + KLM \geq 7$. Therefore this subintegration is no more singular than $\int_0 (\Delta\theta)^{-1/4} d(\Delta\theta)$, which converges. Since all the subintegrations converge, the integral for the whole lattice converges.

The convergence is no accident. All the θ_{α} 's on the whole lattice can be brought arbitrarily close to one another by imposing a sufficiently powerful boost (the headlight effect). But the integration measure has been shown above to be boost invariant.

It is a curious fact that the measure (A.7) is the same as the measure that appears in the computation of the string amplitude for N^4 open-string tachyons on the boundary of a disk. It is a consequence of the $O(1,2)$ symmetry of both systems. The above proof of convergence is the same as that used in string theory.

Figure Captions

Figure 1. Histograms of the cross-link differences $\Delta\theta = \theta_{\alpha} - \theta_{\alpha+\lambda}$ for the exact lattice action (3.2), at $\beta = 10^{-4}$ and $N = 10$, and for the θ -part of the approximate action $S_{\omega,\theta}$ (eq. (6.8)) at $N = 10$. All cross-link differences for 60,000 sweeps have been compiled into 101 bins. The normalized distributions for the two cases are indistinguishable.

Figure 2. Histogram of the s_{α} at $\beta = 10^{-3}$ and $N = 10$, superimposed upon the theoretical Gaussian distribution derived from eq. (6.6) and the ω -part of the approximate action $S_{\omega,\theta}$.

Figure 3. Histogram of the s_{α} at $\beta = 10^{-4}$ and $N = 10$, superimposed upon the theoretical Gaussian distribution derived from eq. (6.6) and the ω -part of the approximate action $S_{\omega,\theta}$.

Figure 4. Plots of $2/\bar{K}^2 \langle \tilde{\sigma}_{Rk}^i \tilde{\sigma}_{Rk}^{i*} \rangle$ vs. $\bar{K}^2/\beta_R$ for various values of β , at $N = 10$. β_R is determined for each curve from its intercept at $\bar{K}^2 = 0$ as obtained from a linear fit to the low-momentum values. The curves are plotted as functions of $\bar{K}^2/\beta_R$ because since $\bar{K}^2/\beta_R$ becomes p^2/μ_R^2 in the continuum limit, this is the only scale-invariant way to compare them. Although the curves are not perfectly smooth they show remarkably little dependence on the detailed values of the components of $\mathbf{k}$. Their essential dependence on $\bar{K}^2$ alone shows that $O(4)$ invariance is maintained in the continuum limit. (See the discussion following eq. (2.15).) The error bars (statistical plus autocorrelation) range from .1% at the high-momentum end to 1% at the low-momentum end. Only the latter are shown on the figure. For $\beta \leq 10^{-3}$ the curves are seen to fall on top of one another at low momenta. The difference between the curves at higher momenta is explained by the spikiness of $\langle \tilde{\sigma}_{Rk}^i \tilde{\sigma}_{Rk}^{i*} \rangle$ arising from $\Omega(\alpha - \alpha')$ in eq. (8.1). The spikiness is a short-wavelength phenomenon that is picked up by the Fourier transform. It goes away as $\beta \rightarrow 0$. The $\beta = 0$ curve itself is obtained by using the θ -part of the action $S_{\omega,\theta}$.

Figure 5. A plot of β_R vs. β as determined from the intercepts of the curves shown in Fig. 4. The error bars, which are less than a tenth of a percent, are almost too small to be seen. At higher values of β the model tends toward a free-field model, and $\beta_R \rightarrow \beta$. It is clear that there is no value of β for which β_R vanishes.

Figure 6. A plot of β_R vs. N when $\beta = 0$, obtained using the θ -part of the action $S_{\omega,\theta}$. The asymptotic value of β_R , as $N \rightarrow \infty$, is approximately .078.

Figure 7. Plots of β_R vs. β at $N = 10$. The black circles represent the values obtained from the σ 2-point function. The triangles represent the values obtained from current-current

averages at low momenta. Error bars are shown only for the triangles. Error bars for the circles are too small to be seen.
